INTRODUCTION

In behaving animals, midbrain dopaminergic neurons fire bursts of action potentials in response to salient stimuli (Redgrave et al., 1990; Horvitz et al., 1997; Schultz, 1998), when a greater than expected reward is received (Schultz et al., 1997), or during sequence learning (Jin and Costa, 2010). The mechanisms by which dopaminergic neurons generate bursts are an area of intense study. The absence of burst firing in slices (e.g., Kita et al., 1986; Grace and Onn, 1989) suggests that bursts are generated in response toafferent input. One view of the dopaminergic neuron in vivo is that single-spiking is generated by an in vitro-like calcium – (Kita et al., 1986; Grace and Onn, 1989; Wilson and Callaway, 2000) or sodium-based (Guzman et al., 2009; Khalil and Bean, 2010) pacemaking mechanism in which spikes can be advanced or delayed due to afferent input. Under such a scheme, bursts are caused by phasic excitatory inputs, e.g., inputs activating AMPA, NMDA, or nicotinic acetylcholine receptors (Grace and Bunney, 1984; Grenhoff et al., 1986; Chergui et al., 1993; Morikawa et al., 2003; Blythe et al., 2007, 2009; Deister et al., 2009; Lobb et al., 2010). However, dopaminergic neurons in vivo are subject to strong tonic synaptic inputs, suggesting that an alternative but complementary mechanism by which dopaminergic neurons may fire bursts is through disinhibition.

Dopaminergic neurons receive strong synaptic activation from spontaneously active inputs in vivo (e.g., Grace and Bunney, 1985; Tepper and Lee, 2007). The effect of these tonic inputs can be seen by subtraction. Local application of NMDA, but not AMPA, receptor antagonists significantly reduce spontaneous burst firing in vivo (Charlely et al., 1991; Overton and Clark, 1992; Chergui et al., 1993; Christoffersen and Meltzer, 1995). Paladin and Tepper (1999), and Brazhnik et al. (2008) found that local application of a variety of GABA_A antagonists by pressure ejection onto the recorded neuron shifted the firing pattern of the dopaminergic neuron from a single-spiking mode to a bursting one, indicating that tonic GABA_A receptor activation was strong enough to suppress burst firing. These experiments suggest that dopaminergic neurons are subject to at least two types of tonic inputs in vivo: an NMDA-mediated excitatory input and a GABA_A-mediated inhibitory input. We have recently demonstrated that dopaminergic neurons that receive tonic NMDA and GABA_A inputs can maintain their spontaneous activity and are capable of generating bursts through disinhibition (Lobb et al., 2010). Using a combination of network and compartmental computational modeling, we explore how disinhibition bursting of dopaminergic neurons might arise from striatal activation.

MATERIALS AND METHODS

This study investigated conditions under which disinhibition in the basal ganglia network leads to bursting in midbrain dopaminergic neurons. Our model was based on a combination of two previously published models. The first is the current-based, integrate-and-fire type network model of the basal ganglia described in Humphries et al. (2006). This network model was used to generate the synaptic input onto a two-compartment model of a substantia nigra pars compacta (SNpc) dopaminergic neuron (Kuznetsov et al., 2006).
The network model contained five collections of neurons: D1STR (D1-expressing striatum, N = 64 neurons, threshold θ = 30 mV, time constant τm = 25 ms), globus pallidus (GP; N = 64, θ = 30 mV, τm = 14 ms), STN (N = 64, θ = 20 mV, τm = 6 ms), substantia nigra pars reticulata (SNpr; N = 64, θ = 30 mV, τm = 8 ms), and SNpc (N = 64, see single cell model below). See Humphries et al. (2006) for the full specification of the model.

The original Humphries et al. (2006) model consists of multiple anatomically based microchannels to allow for a mechanism of action selection. For simplicity, we employed only a single microchannel. Connections were added between nuclei as shown in Figure 1. The D1STR–SNpc connection arises from neurons in striatal patches whereas the D1STR–SNpr connection arises from neurons in the striatal matrix (Gerfen, 1984). It is unclear if both would be activated during a rewarding scenario and thus the D1STR–SNpc connection is disregarded in this study. All connections were given a weight of −1, 0, or +1, where a negative value represents an inhibitory connection and a positive value represents an excitatory connection. Connections could be removed or disabled in the network by setting the connection weight to zero. An afferent neuron made a synaptic connection onto each neuron in the network by setting the connection weight to zero. An excitatory connection. Connections could be removed or disabled in the network by setting the connection weight to zero. An afferent neuron made a synaptic connection onto each neuron in a target nucleus with a probability of 0.25. As described in Humphries et al. (2006), inhibitory connections were modeled as exponentially decaying negative currents with a decay time τGABA = 3 ms. Excitatory connections had both AMPA and NMDA components, each modeled as a simple decaying exponential with decay times τAMPA = 2 ms and τNMDA = 100 ms. The peak amplitude of individual AMPA and GABA, post synaptic potentials were 3 mV; individual NMDA potentials peaked at 0.1 mV. Dopamine levels were set to the “normal” condition in Humphries et al. (2006; λD1 = λD2 = 0.3). Background pacemaking activity seen in basal ganglia neurons (STN: 12 Hz, GP: 26 Hz, SNpr: 32 Hz) was induced by injecting a suprathreshold fixed current. The level of this current was adjusted to maintain background firing rates for the reduced model described in Figures 3–5 (STN: 66.1 pA, GP: 17 pA, SNpr: 14 pA) and the full model described in Figures 6 and 7 (STN: 100.5 pA, GP: 17 pA, SNpr: 26 pA). As described in Humphries et al. (2006), each neuron model contained a noise term with a mean ± SD of 0 ± 0.0008 mV.

Disinhibition bursts were initiated by modeling bursts of cortical inputs as step pulses of current delivered to D1STR neurons (+2 nA, 150 ms). Simulations were run for 1 s before these current injections to mitigate any effect of onset transients. Simulations were implemented in MATLAB (Mathworks, Natick, MA, USA) as described in Humphries et al. (2006).

Inputs to the single cell SNpc model arose from the SNpr, GP, and STN. The SNpr and GP inputs made synapses onto both somatic and dendritic compartments of the two-compartment model and activated postsynaptic GABA receptors on dopaminergic neurons (Paladini and Tepper, 1999). STN inputs made synapses onto the burst-generating, dendritic compartment of the two-compartment model and activated postsynaptic NMDA receptors. Postsynaptic activation of AMPA receptors was excluded because local application of an AMPA receptor antagonist in vivo does not change the activity of dopaminergic neurons (Chergui et al., 1994). In contrast, tonic STN input contributes to spontaneous bursting in vivo (Smith and Grace, 1992; Chergui et al., 1994) that is strongly affected by local application of NMDA receptor antagonists (Chergui et al., 1994). GABA-released currents were added to both somatic and dendritic compartments of the two-compartment dopaminergic neuron model.

The synaptic conductances waveforms were described as a difference of exponentials: Gsyn(t) = δ[δ∗(e−t/τAMPA − e−t/τNMDA)]. Spike times were drawn from activation in the network model and each triggered a step increase of size δ. For GABA, receptors (input from GP and SNr), τrise = 1 ms, τfall = 6 ms, and δGABA = 0.043 ms/cm². For NMDA receptors (input from STN), τrise = 3 ms, τfall = 40 ms, and δNMD = 0.030 ms/cm².

Single cell simulations were run in XPPAUT (Ermentrout, 2002) using the RUNGE–KUTTA method with dt = 0.01 or 0.005 ms. Bifurcation diagrams were made with the XPPAUT implementation of AUTO. Equations were implemented as described in the original model and are not reproduced here. The full set of parameters used here is given in Table 1. Calcium buffering parameters are identical to the original model with the exception of the calcium pump density, which was increased from 2500 to 10,000 μm/s to increase the frequency of dopaminergic neuron bursting produced in the model.

RESULTS
SINGLE CELL
We first investigated the range of synaptic parameters that can give rise to bursting in our single cell model of the midbrain dopaminergic neuron. When all the synaptic conductances are set to 0, the dopaminergic neuron shows a very regular pattern of spiking at a frequency of approximately 4–5 Hz (Figure 2A). The model can generate a sustained burst in response to a phasic NMDA conductance (Figure 2B; $g_{\text{NMDA}} = 0.28 \text{ ms/cm}^2$ at 1100 ms). Bursts could also be generated through disinhibition. Constant NMDA and GABA$_\Lambda$ conductances were applied to the model to maintain balanced spiking (Figure 2C; $g_{\text{GABA}} = 0.14 \text{ ms/cm}^2$, $g_{\text{NMDA}} = 0.28 \text{ ms/cm}^2$). At $t = 1100$ ms the GABA$_\Lambda$ conductance was set to 0 and the cell fired a sustained burst of action potentials (intra-burst frequency in Figure 2B,C are both 47 Hz).

Given that dopamine neuron bursting can result from either an increase in excitation or a removal of inhibition, we determined which combinations of GABA$_\Lambda$ and NMDA conductance values permitted repetitive spiking. In particular, we calculated a two-parameter bifurcation diagram that separated oscillatory (repetitive spiking) behavior from fixed-point (non-spiking) behavior (Figure 2D). The hatched region represents combinations of synaptic conductances for which the cell fires trains of action potentials. Parameters below to the right of this hatched region correspond to situations in which firing is prevented by too much inhibition. Note that firing is also absent above and to the left of the hatched region. For these parameters, the model enters depolarization block and ceases to fire, a problem that is even more severe for AMPA-mediated, vs. NMDA-mediated, excitation (Deister et al., 2009).

The shape of the firing region suggests that disinhibition may be more robust than excitation as a mechanism for burst generation. This is because for most starting conditions, the system will remain in the firing regime even after a complete removal of inhibition. In contrast, NMDA conductance values must stay within a bounded region to support burst firing. Too much excitation and the system will move vertically outside the oscillating region and cease firing due to depolarization block.

This firing region was [$\text{Mg}^{2+}$] dependent (Figure 2E). Increasing Mg$^{2+}$ RUNGE–KUTTA method concentrations reduces the negative slope conductance of the NMDA conductance, and the firing region becomes elongated. Under these conditions, the action of disinhibition and excitation are more similar in that removing too much inhibition will also drive the model into depolarization block and shut off bursting.

**FIGURE 2** The dopaminergic neuron can fire disinhibition bursts.

(A) Spontaneous, single-spiking in the absence of tonic input in a two-compartment model of the dopaminergic neuron. (B) Phasic activation of NMDA receptors (at $t = 1100$, 150 ms) produces a burst of action potentials. (C) The model exhibits single-spiking at similar frequencies as in (A) and can produces bursts by disinhibition upon complete removal of tonic inhibition at $t = 1100$ ms for 150 ms. (D) The NMDA and GABA$_\Lambda$ conductances at which repetitive spiking can be generated (hatched region) is computed by a two-point bifurcation diagram in AUTO (XPPAUT). (E) Magnesium dependence of the oscillatory region.
of cortical input. Outputs from the network model were read into XPPaut and incremented their respective conductance equations by δ. These values were estimated such that the mean conductance was approximately $g_{\text{GABA}} = 0.14 \text{ ms/cm}^2$ and $g_{\text{NMDA}} = 0.28 \text{ ms/cm}^2$. An example is shown in Figure 3. Stimulation of the striatum evoked a burst in the dopaminergic neuron. The number of spikes in that burst was dependent on the length of time in which the striatum was stimulated (Figures 4B,C; 30–150 ms). The intra-burst firing frequency, however, was unaffected (Figure 4A).

**DIRECT PATHWAY**

After considering the single cell model in isolation, we investigated how disinhibition bursts could be driven by synaptic input patterns resulting from a network model of the basal ganglia based on the model of Humphries et al. (2006; see Materials and Methods). We first considered the influence of the D1STR–SNpr–SNpc (“direct”) pathway. All connections other than the D1STR–SNpr, SNpr–SNpc, STN–SNpr, and STN–SNpc were disabled. Neurons in D1STR received direct current injection intended to model a burst of disinhibition bursts can be evoked by striatal stimulation in the reduced Humphries et al. (2006) model. Raster plots for the 64 neurons in the D1 striatum, STN and SNpr. The only connections present in the reduced model were D1 striatum to SNpr, STN–SNpc, STN–SNpr, and SNpr–SNpc. At 1 s all 64 D1 striatal projection neurons were activated by current injection for a period of 150 ms. The simulation was run for a total of 10 s. The input to a random SNpc neuron was captured, saved to a file, and read in by the modified Kuznetsov et al. (2006) model. The synaptic conductances and resulting trace are shown below. Conductances were initially set at zero. The dopaminergic neuron model fired single spikes at approximately 5 Hz and exhibited a burst of action potentials during the period of striatal stimulation.

**FIGURE 3** | Disinhibition bursts can be evoked by striatal stimulation in the reduced Humphries et al. (2006) model. Raster plots for the 64 neurons in the D1 striatum, STN and SNpr. The only connections present in the reduced model were D1 striatum to SNpr, STN–SNpc, STN–SNpr, and SNpr–SNpc. At 1 s all 64 D1 striatal projection neurons were activated by current injection for a period of 150 ms. The simulation was run for a total of 10 s. The input to a random SNpc neuron was captured, saved to a file, and read in by the modified Kuznetsov et al. (2006) model. The synaptic conductances and resulting trace are shown below. Conductances were initially set at zero. The dopaminergic neuron model fired single spikes at approximately 5 Hz and exhibited a burst of action potentials during the period of striatal stimulation.
What percentage of the medium spiny neurons must become activated to sufficiently inhibit the SNpr neurons to cause disinhibition bursting in the SNpc? In the previous simulations, all of the medium spiny neurons in the D1STR were stimulated at \( t = 1000 \text{ ms} \). Changing the probability that a D1STR neuron was stimulated had a large effect on the intra-burst firing frequency and the number of spikes in the burst (Figure 5). The probability for which an individual D1STR neuron was stimulated was set to 0.03 (1 of 64 cells activated), 0.1, 0.25, 0.4, 0.6, 0.8, or 1.0. A high frequency burst of a significant number of spikes was generated in response to a stimulation of only a few neurons (Figure 5). Thus, even weak striatal stimulation can evoke bursts in dopaminergic neurons.

**FIGURE 4 |** Length of striatal stimulation controls the number of spikes in the disinhibition burst but not the intra-burst firing frequency. (A) Shows the intra-burst firing frequency of the disinhibition burst (max. black, mean gray). (B) Shows the number of spikes in the burst. A raster plot of the results is shown in (C).

**FIGURE 5 |** Weak striatal stimulation can cause disinhibition bursts. The probability that a striatal cell will be stimulated at \( t = 1000 \text{ ms} \) in the reduced Humphries model is varied. (A) Shows the intra-burst firing frequency of the disinhibition burst (max. black, mean gray). (B) Shows the number of spikes in the burst. A raster plot of the results is shown in (C).
INDIRECT AND DIRECT PATHWAYS

Do dopaminergic neurons still evoke a burst when the indirect pathway is included in the model? The connections between GP–SNpc, GP–STN, STN–GP, GP–SNpr, and STN–SNpr were enabled. The constant current parameter for each cell type was modified such that the firing rates of the STN and SNpr were similar to the simulations presented in the previous section. Bursts were still evoked upon stimulation of all striatal neurons (Figure 6). Note that the inhibition is not completely removed during striatal stimulation. When the above indirect pathway connections were enabled in the network model, SNpc dopaminergic neurons received tonic inhibitory input from two sources: SNpr and GP. In the simulations shown in Figure 6, only SNpr neurons were inhibited upon D1STR stimulation. Thus, disinhibition need not be an all-or-none phenomenon (e.g., Lobb et al., 2011).

D1STR neurons projecting to the SNpr give off collaterals that terminate in the GP (Kawaguchi et al., 1990; Parent et al., 1995). This connection was added to the network model. Disinhibition bursting was enhanced by inclusion of the D1STR–GP connection (Figure 7). An example is shown in Figure 7A for a D1STR–GP weight of −1.0. Near-maximal frequency bursting could be obtained with a connection strength of only 0.2 (in comparison with other connections, which have a weight of ±1.0). The enhancement in SNpc activity is due to an inhibition of both GP and SNpr neurons (disinhibiting SNpc neurons) and a disinhibition of the STN through the GP (strongly exciting SNpc neurons). This suggests that striatal activation is a robust means by which bursts can be generated by SNpc dopaminergic neurons.

DISCUSSION

In this paper, we used computer simulations with network-generated time-varying conductances to explore disinhibition bursting in the basal ganglia. We first showed that the two-compartment single cell model of the dopaminergic neuron maintained its ability to fire trains of action potentials when tonic NMDA and GABA_\text{A} conductances were applied. We then used a bifurcation analysis to map out the combinations of NMDA and GABA_\text{A} conductances for which the model was able to produce sustained trains of action potentials. As expected, increasing inhibition or lowering excitation shifts the dopaminergic neuron into the non-oscillatory region, resulting in a pause in spiking (as seen in Figure 3A of Lobb et al., 2010). The bifurcation analysis revealed that large increases in excitation can also cause the dopaminergic neuron to cross into the non-oscillatory region, with the cessation of spiking due to a depolarization block of sodium mediated action potentials. In contrast, for moderate levels of the NMDA conductance, spiking was maintained even after complete removal of inhibition.

Disinhibition bursts could be evoked through the D1STR–SNpr–SNpc pathway by phasic activation of the D1STR. The duration of the striatal stimulation is an important determinant of the number of spikes in the burst, but has little effect on its intra-burst firing frequency. Striatal inhibition of the SNpr is powerful and thus only a small percentage of striatal cells need to be activated to evoke a burst in dopaminergic neurons.

Tonic inhibition onto dopaminergic neurons is a combination of inputs from GP and SNpr. In our simulations, the firing rate of the GP and SNpr were similar, and thus silencing of the SNpr would only remove that percentage of the tonic inhibition. The burst in SNpc neurons is affected by the percentage of tonic inhibition that is removed by a disinhibitory stimulus such as striatal activation; specifically, increased removal of inhibition increases the intra-burst firing frequency of the disinhibition burst (Lobb et al., 2011).

Disinhibition of the SNpc was enhanced by including a collateral from D1STR to the GP. This was due to an inhibition of the GP (thereby disinhibiting SNpc) and subsequent disinhibition of the subthalamic nucleus (thereby exciting the SNpc). Another interesting question that

**FIGURE 6** Tonic inhibition by GP reduces direct pathway mediated disinhibition bursting in the Humphries et al. (2006) model. In the Humphries model, tonic inhibition is provided by both the GP and SNpr. All connections are added except the D1STR–GP connection. Since GP and SNpr have similar firing rates, silencing of the SNpr by striatal stimulation removes approximately half of the inhibition at t = 1000 ms. Disinhibition bursts can still be produced.
The D1STR–GP connection promotes burst firing. (A) The D1STR–GP connection was added with a weight of −1.0. The synaptic conductances generated in the network model from the STN (red), GP (green), and SNpr (blue) are shown on the top. The resulting voltage trace is shown below. (B) Shows the intra-burst firing frequency of the disinhibition burst (max black, mean gray) as a function of the D1STR–GP weight. (C) Shows the number of spikes in the burst. A raster plot of the results is shown in (D). To avoid ceiling effects, in these simulations \( \delta \) was reduced to \( \delta_{\text{GABA}} = 0.0043 \text{ ms/cm}^2 \) and \( \delta_{\text{NMDA}} = 0.0030 \text{ ms/cm}^2 \) so that the mean tonic conductances were approximately \( g_{\text{GABA}} = 0.02 \text{ ms/cm}^2 \) and \( g_{\text{NMDA}} = 0.04 \text{ ms/cm}^2 \).
In this model, only some of the basic features of these connections are implemented. Many features, such as a high degree of convergence from one nucleus onto another, the action of neuromodulators, synaptic enhancement or depression, and the presence of correlated activity within different nuclei are not included. We anticipate that factors such as these may play a large role in determining the weights of each connection and thus could have a major impact on bursting. Similarly, we have focused on stimulation of the D1-containing medium spiny neurons. Cortical activation of D2-containing medium spiny neurons may also evoke bursting in dopaminergic neurons similar to our results above. Finally, cortical activation may also evoke strong excitation in subthalamic neurons via the hyperdirect pathway. However, unlike striatal stimulation, activity in the presence of correlated activity within different nuclei are not focused on stimulation of the D1-containing medium spiny neurons: possible preferential role for N-methyl-D-aspartate receptors.
